Summary

Permafrost degradation may cause strong feedbacks of arctic ecosystems to global warming, but this will depend on if, and to what extent, organic matter (OM) is protected against biodegradation by mechanisms other than freezing and anoxia. Here, we report on the amount, chemical composition and bioavailability of particulate (POM) and mineral-associated OM (MOM) in permafrost soils of the East Siberian Arctic. The average total organic carbon (OC) stock across all soils was 24.0 ± 6.7 kg m⁻² within 100 cm soil depth. Density fractionation (density cut-off 1.6 g cm⁻³) revealed that 54 ± 16% of the total soil OC and 64 ± 18% of OC in subsoil horizons was bound to minerals. As well as sorption of OM to clay-sized minerals ($R^2$ = 0.80; $P < 0.01), co-precipitation of OM with hydrolyzable metals may also transfer carbon into the mineral-bound fraction. Carbon:nitrogen ratios, stable carbon and nitrogen isotopes, $^{13}$C-NMR and X-ray photoelectron spectroscopy showed that OM is transformed in permafrost soils, which is a prerequisite for the formation of mineral-organic associations. Mineral-associated OM in deeper soil was enriched in $^{13}$C and $^{15}$N, and had narrow C:N and large alkyl C:(O-/N-alkyl C) ratios, indicating an advanced stage of decomposition. Despite being up to several thousands of years old, when incubated under favourable conditions (60% water-holding capacity, 15°C, adequate nutrients, 90 days), only 1.5–5% of the mineral-associated OC was released as CO₂. In the topsoils, POM had the largest mineralization but was even less bioavailable than the MOM in subsoil horizons. Our results suggest that the formation of mineral-organic associations acts as an important additional factor in the stabilization of OM in permafrost soils. Although the majority of MOM was not prone to decomposition under favourable conditions, mineral-organic associations host a readily accessible carbon fraction, which may actively participate in ecosystem carbon exchange.

Introduction

An increase in surface air temperatures, as already experienced during recent decades, facilitate permafrost thaw and promote active layer deepening, thermokarst formation, and river and coastal erosion (Fountain et al., 2012). The most important consequences of climate change in permafrost environments are gradual or sometimes abrupt changes in the soil environmental conditions (such as thermal and moisture regime, and aeration) with direct consequences on organic carbon (OC) destabilization (Ping et al., 2015). Long-term preserved OC will get increasingly exposed to microbial decomposition and be released from the active layer and the previously frozen ground to the atmosphere as CO₂ and...
CH₄ (Nowinski et al., 2010) or discharged by the drainage system (Vonk et al., 2013). Warming of permafrost soils is also predicted to result in larger nutrient availability caused by new inputs of OC from shifting plant communities, increasing plant productivity and the spread of deep-rooting plant species (Hartley et al., 2012). Under these conditions, priming reactions induced by the addition of fresh carbon sources might facilitate the release of older OC from subsoil horizons (Wild et al., 2014). However, the magnitude of the processes stimulating OC loss from mineral soil horizons strongly depends on the soil parent material and the protective capabilities of the soil minerals.

Mineral-organic associations play a crucial role in soil organic matter (OM) preservation and mineral-associated OM (MOM) often accounts for the majority of total soil carbon (Kleber et al., 2015). Variation in the mineral assemblage has been reported to not only alter the OC contents and the composition of OM but also its bioavailability (Mikutta et al., 2007). In this context, MOM is considered to be an amorphous structure of variable composition and bound to single or multiple mineral surfaces. In permafrost soils, the frequent moderately acidic to neutral pH (Alekseev et al., 2003) and anoxic conditions, which induce the reduction of Fe(III) oxyhydroxides (Lipson et al., 2012), might impair the stabilization of OM by Fe oxides in the subsoil. Despite the importance of OC preservation through mineral interactions, only a few studies have addressed the dynamics of MOM in high-latitude soils (Gundelwein et al., 2007; Höfle et al., 2013; Jagadamma et al., 2013) and very little is known about the role of minerals in terms of their ability to sorb and stabilize OM.

Compared with OC that is attached to minerals, particulate OM (POM) from decaying plant material represents a more bioavailable carbon fraction (Schrumpf et al., 2013). Such organic debris can accumulate close to the permafrost surface or within the permafrost as a consequence of cryoturbation (vertical soil mixing upon frequent freeze-thawing cycles) and is stabilized there over longer periods (Kaiser et al., 2007). In contrast to the recognition that POM is more degradable than OM associated with minerals, Jagadamma et al. (2013) showed that, unlike for other soil types such as Andisols, Mollisols, Ultisols and Oxisols, MOM and POM from a Gelisol were decomposed at comparable rates during an incubation experiment and that MOM in the Gelisol tended to be respired faster than that from the other soils. Therefore, knowledge on the transformation of OM, its distribution in functional fractions across different soil horizons, and their potential decomposability, is important in order to assess the overall stabilization potential of OM in permafrost soils. Consequently, the main objectives of this study were to (i) investigate the soil mineralogical composition and quantify the OC portion associated with the mineral phase versus the OC proportion bound in POM, (ii) determine the degree of OM decomposition and (iii) test the potential bioavailability of MOM in comparison with POM. Organic matter fractions of permafrost soils were physically isolated by density separation and characterized for stable isotopes (¹³C and ¹⁵N), and their chemical composition was determined with solid-state ¹³C nuclear magnetic resonance and X-ray photoelectron spectroscopy. Finally, both MOM and POM fractions were incubated for 90 days under optimal nutrient and temperature conditions to assess their potential bioavailability.

Materials and methods

Soil sampling and terminology

For this study we sampled three tundra ecosystems of northeastern Siberia along the lower Kolyma River, Russia (Figure 1): shrubby grass tundra (SG), shrubby tussock tundra (ST) and shrubby lichen tundra (SL). Detailed descriptions of the sites and sampling design are given in File S1 and Gentsch et al. (2015). Diagnostic horizons of three replicated 5 m soil trenches per tundra type were sampled (Figure 2), including two soil cores from the upper 45 cm of the permafrost. Bulk density (BD) samples from each horizon were taken in triplicate with 100 cm³ stainless steel core cutters.

All soils showed strong signs of cryoturbation with hummock topography or bare frost boils being located adjacent to vegetated...
Depressions or cracks (Figure 2). Depressions had aquic moisture regimes and strong accumulation of OM. The soils were classified as Cryosols according to the IUSS Working Group WRB (2014) or Gelisols according to USDA Soil Taxonomy (Soil Survey Staff, 2010) (Table 1). Pockets of OM-enriched material (compared with topsoil materials) transferred into the subsoil by cryoturbation were sampled from several locations within the active layer; in the following these are referred to as ‘subducted topsoil’. Living roots and macroscopic soil fauna were removed from all soil samples before they were dried and sieved to < 2 mm. The following terminology is used to summarize diagnostic soil horizons (symbols according to Soil Taxonomy): organic topsoil (O, Oa, Oe), mineral topsoil (A, AB), subducted topsoil (Oj, Aj) and subsoil horizons (BCg, Cg, Cff).

Soil characteristics

The texture composition was determined by the standard sieve-pipette method after removal of OM and Fe oxides (DIN ISO 11277, 2002). The effective cation exchange capacity (CECeff) was determined by extraction of soils with a Mehlich-3 solution (Ziadi & Tran, 2006); the extracted cations were measured by inductively coupled plasma optical emission spectroscopy (ICP-OES; Varian 725-ES, Varian Australia Pty Ltd, Mulgrave, Australia). The base saturation (BS) was calculated as percentage contribution of the basic cations (Ca, Mg, K and Na) to CECeff. Pedogenic Fe and Al fractions were determined by standard dithionite-citrate-bicarbonate (Fed) and acid oxalate extraction (Feo, Alp) according to Pansu & Gautheyrou (2006). The Fed extract represents the amount of pedogenetically formed Fe within (hydr)oxides and silicates, as well as in organic complexes capable of acting as an electron acceptor, whereas Feo and Alp originate from poorly crystalline aluminosilicates, ferrhydrite, Al-gels and Al- and Fe-organic complexes. Oxalate-soluble Fe also reflects the proportion of pedogenic Fe that dissolves in the initial stage of the dissimilatory Fe(III) reduction but may also contain some Fe extracted from biotite (Vodyanitskii et al., 2008). The ratio Feo/Fe2+ reflects the portion of poorly crystalline Fe oxides to total pedogenic Fe oxides. Organically complexed Fe and Al (Feo, Alp) were determined by extraction of mineral-organic associations by 0.1 M sodium-pyrophosphate solution adjusted to pH 9.0 and shaken for 16 hours. In order to avoid the dispersion of Fe and Al colloids, extracts were centrifuged at 300,000g for 6 hours and Fe and Al in the supernatant liquid were measured by ICP-OES. Soil pH was measured in a soil-water suspension at a ratio of 1:2.5. The clay mineral composition of Fe-oxide and OM-free clay samples saturated with either K+ (including heating to 550°C), Mg2+ or Mg2+/glycol was determined by X-ray diffraction (Kristalloflex D500, Siemens AG, Mannheim, Germany) by CuKα radiation, at a step size of 0.05° and 10-s acquisition per time-step. Identification of the most abundant clay minerals was as outlined in section S1 of File S1.

Density fractionation, soil organic matter analyses and carbon storage

Density fractionation using sodium polytungstate (SPT; density cut-off 1.6 g cm-3) was used to separate POM and MOM in mineral soil horizons. Because the investigated soils had a plastic consistency and little sign of aggregation, we did not isolate an aggregate-occluded POM fraction as is routine for non-permafrost soils. Twenty-five grams of soil were dispersed in 125 ml SPT for about 10 minutes with a total sonication energy of 60 J ml-1 using a LABSONIC® ultrasound homogenizer (Sartorius Stedim Biotech GmbH, Göttingen, Germany). The floating POM fraction was separated from the heavier MOM fraction by decantation after settling for 1 hour and centrifugation (3500 g; for 10 minutes). Both fractions were washed with 18-MΩ water until the electrical conductivity was < 50 μS cm-1, and freeze-dried. For samples with incomplete recovery of POM, the procedure was repeated without sonication until no POM remained floating. During the cleaning from SPT remnants, considerable amounts of OC and TN were mobilized from the MOM fraction. This mobilized fraction (MoF) was quantified by mass balance (Table 3) and may contain OM components that in soil might also easily move into the soil solution. Organic carbon and total nitrogen as well as the isotopic composition (13C and 15N) of fractionated and bulk samples were measured with an IsoPrime 100 IRMS (IsoPrime Ltd, Cheddie Hulme, UK) coupled to an Elementar vario MICRO cube (Elementar Analysensysteme GmbH, Hanau, Germany). Traces of carbonates (< 0.5%) were removed by acid fumigation according to Harris et al. (2001) and subsequent neutralization was carried out over NaOH pellets (for 48 hours each). The δ13C and δ15N values of soil samples were corrected by calculating response factors determined by linear regressions between measured 13C or 15N contents and respective δ13C or δ15N values of standard compounds (for 13C, sucrose, glutamic acid and caffeine; for 15N, glutamic acid and caffeine, IAES (NH4)2SO4 standards). The 13C and 15N values were expressed in the delta notation related to the Vienna PeeDee-Belemnite-Standard (~20‰) and atmospheric N2 (0‰), respectively. Dissolved OC (DOC) was quantified by extraction of soil with bi-distilled water (organic horizons: 1:10 w:v; mineral horizons: 1:20 w:v) for 2 hours. The filtered extracts (0.45 μm; MN-GF 5, MACHEREY-NAGEL, Düren, Germany) were analysed for DOC by a LiquiTOC analyser (Elementar Analysensysteme GmbH).

The radiocarbon content (Δ14C) of selected OM fractions was determined by accelerator mass spectrometry at the Klaus-Tschira-Laboratory for Radiometric Dating Methods at the Curt-Engelhorn-Centre for Archaeometry GmbH, Germany. Homogenized samples were pretreated by rinsing with 0.5 M HCl to remove traces of carbonates. The 14C results were expressed in as a percentage of modern carbon (pMC), and conventional 14C ages were calculated according to Stuiver & Polach (1977) and referenced to 1950 (1950 A.D. = 0 B.P.)

Solid-state cross-polarization magic angle spinning 13C-NMR analyses of ground OM fractions were made with a Bruker DSX 200 instrument (Bruker Biospin GmbH, Karlsruhe, Germany). Samples were filled into zirconium dioxide rotors and spun in a magic
angle spinning probe at 6.8 kHz to minimize chemical anisotropy. A ramped 1H pulse was used during a contact time of 1 ms to prevent Hartmann–Hahn mismatches. The delay times ranged from 400 ms for MOM fractions to 1000 ms for POM fractions. Chemical shifts were referenced to tetramethylsilane (TMS = 0 ppm). Prior to analysis, the MOM fractions were treated with 10% hydrofluoric acid to remove mineral material, including paramagnetic compounds such as iron, and to concentrate OM (section S3, File S1). For integration, the following chemical shift regions were used: alkyl C (–10 to 45 ppm), O/N-alkyl C (45–110 ppm), aryl/olefine C (110–160 ppm) and carbonyl/carboxyl/amide C (160–220 ppm) (Höfle et al., 2013).

X-ray photoelectron spectroscopy (XPS) was applied to nine MOM samples (the same number as used for $^{13}$C-NMR) to study the composition of OM at the outermost mineral-organic interface (top ~10 nm). The samples (~63 μm) were deposited onto adhesive copper-nickel tape and analysed by a Kratos Axis Ultra DLD instrument (Kratos Analytical Ltd, Manchester, UK). The scans for survey spectra (pass energy, 160 eV; step size, 1 eV) and C1s detail spectra (pass energy, 10 eV; step size, 0.1 eV) were acquired in the hybrid lens mode with photoelectrons originating from an area of 300×700 μm. After charge correction, the C1s peak centered at 285 eV was de-convoluted into several sub-peaks representing different carbon oxidation states by least square fitting (Mikutta et al., 2014).

The OC stocks of the soils were quantified from the digitized 5-m² soil profiles by multiplying the area of a specific horizon with the bulk density and OC concentration (Gentsch et al., 2015).

**Incubation experiment**

In order to test the potential bioavailability of OM fractions in comparison to the bulk soil in different soil horizons, 10 POM samples, 18 MOM samples and 18 bulk soil samples were incubated in triplicate for 90 days at 60% water-holding capacity and 15°C in the dark. A Hoagland’s solution provided all the necessary macro- (N, P, K, Ca, Mg and S) and micro-nutrients (Fe, Mn, Mo, B, Zn and Cu). We applied a purified quartz-silt mixture to ensure the same OC contents (50 mg total OC), substrate mass (20 g) and water-holding capacity in all treatments. Samples were inoculated with a solution containing $10^6$ cells (determined by SYBR Green staining and fluorescence microscopy) extracted from a mixture of all 18 horizons (mineral top- and sub-soils, subducted topsols and permafrost from all three tundra types). Previously, the microbial community in the soil mixture was reactivated with a 28-day incubation in the dark at 15°C and 60% water-holding capacity and thereafter extracted with 0.004 m CaCl$_2$ and filtered through 5–8-μm cellulose filters. After addition of the inoculum, the flasks were closed by polyethylene wool to allow for gas exchange with the atmosphere. Pre-equilibration of soil and OM fractions before the first gas sampling lasted for 7 days to avoid the rewetting-induced CO$_2$ pulse. Twenty-four hours before each gas sampling the flasks were closed and flushed with CO$_2$-free air. Gas samples were transferred to 20-ml pre-evacuated vials at days 0, 7, 14, 21, 28, 42, 56 and 90. Carbon dioxide emissions were measured with a GC equipped with an electron capture detector (Shimadzu GC 2014, Kyoto, Japan) and corrected for the CO$_2$ release from an inoculated quartz powder. Bulk soils were incubated analogously. Because of the similar mineralization rates of bulk OM

compared with the density fractions, we can rule out toxic effects caused by tungsten residues (present at <1 atom% on mineral surfaces based on XPS) during incubation of the MOM and POM. Averaged cumulative mineralization curves were most accurately described by a first-order decay model: \( f = a \times \exp(-kt) \), where \( f \) is the remaining OC calculated from CO2 loss (mg OC g\(^{-1}\) OC), \( a \) is the fitted initial OC concentration scaled to one gram of OC, \( k \) is the decomposition rate constant, and \( t \) the time. Note, the first-order decay model was applied to derive mineralization rates without underlying assumptions regarding the number of rate-limiting reactants or presence of multiple OC pools.

**Statistics**

Pearson correlation coefficients between soil, OM and incubation conditions, as well as regression analyses, were calculated with the software package SPSS Statistics vs. 21. If necessary, the data were log transformed to achieve a normal distribution. Differences between medians of properties were tested by the non-parametric Mann–Whitney U-test. Differences between soil horizons and incubation treatments were explored using analysis of variance (ANOVA), setting horizons and treatments as fixed or random effects, respectively. Significant differences within horizons or treatments were compared by the least significant difference (LSD) test. The figures 3 and 9 were produced with the R packages lattice and ggplot2.

**Results and discussion**

**Mineral and organic matter properties**

The soils had developed on late Pleistocene sediments and were all rich in silt (mean ± SD; 74 ± 8%; \( N = 86 \); Table 2), with smaller contributions of clay (21 ± 8%) and sand (6 ± 3%). Soil pH\(_{\text{water}}\) values ranged from 4.8 to 8.1, with smaller values in the organic and mineral topsoil horizons and larger ones in the mineral subsoils (Table 2). The CEC\(_{\text{eff}}\) of all analysed horizons ranged between 20 and 35 cmolc kg\(^{-1}\) and the base saturation varied from 36 to 67% (Table 2), implying that weathering of the tundra soils released considerable amounts of acidic cations (primarily Al), which were subsequently present in the exchange complex. Calcium and Mg\(^{2+}\) contributed on average 47 ± 9% to the exchange capacity: inclusion of Al\(^{3+}\) increased this portion to 94 ± 2%. Concentrations of total pedogenic soil Fe (Fe\(_{\text{tot}}\)) were between 7 and 12 g kg\(^{-1}\) soil and similar to those reported in Vodyanitskii et al. (2008). A large proportion of Fe resided in forms capable of being reduced within a short time, such as ferrhydrite, as also indicated by average Fe\(_{\text{ox}}\):Fe\(_{\text{tot}}\) ratios of between 0.39 and 0.95. Organo-complexed Fe and Al were more enriched in subducted topsoil horizons (Fe\(_{\text{ox}}\), 2.3–7.1 g kg\(^{-1}\); Al\(_{\text{ox}}\), 1.1–6.6 g kg\(^{-1}\); Table 2) than in adjacent subsoil horizons (Fe\(_{\text{ox}}\), < 1.5 g kg\(^{-1}\); Al\(_{\text{ox}}\), < 0.6 g kg\(^{-1}\)). The X-ray diffraction of clay fractions from selected soil horizons revealed a fairly homogeneous clay mineral assemblage dominated by ordered, expandable interstratified minerals (1.4–1.7 nm), vermiculite, chlorite, illite and kaolinite (Figure 3; Figure S1, File S1). The minor variation of clay minerals in the different tundra soil horizons might indicative a homogeneous aeolian parent material or the mixing of soil material by cryoturbation ('cryo-homogenization'). While kaolinite is of detrital origin, the slight change from illite towards vermiculite in topsols (Figure 3) reflects abundant but slow chemical weathering in these high-latitude soils (Borden et al., 2010).

Average OC concentrations in the soils were largest in the organic topsoil, followed by the subducted topsoil horizons (Ajj/Ojj) where

CEC\(_{\text{eff}}\), effective cation exchange capacity; BS, base saturation; Fe\(_{\text{ox}}\), Fe extractable in dithionite-citrate-bicarbonate; Fe\(_{\text{ox}}\) and Al\(_{\text{ox}}\), Fe and Al extractable in acid oxalate; Fe\(_{\text{ox}}\) and Al\(_{\text{ox}}\), pyrophosphate-extractable Fe and Al, respectively; SD, standard deviation; nd, not determined.
average values for the three tundra types ranged between 68 and 155 mg OC g\(^{-1}\) soil, and smallest in the mineral subsoil (BCgjj and Cgjj) and permafrost (Cff) horizons (Schnecker et al., 2014). Total OC stocks of the soils ranged between 15 and 33 kg m\(^{-2}\) OC (average 24 ± 6 kg m\(^{-2}\)) within the upper 100 cm, with only slight differences among the tundra types (Gentsch et al., 2015; Table S1, File S1). When considering all soil pedons \(N = 9\), 36 ± 20% of the total OC stocks were in the upper permafrost, while 20 ± 12 and 13 ± 4% were stored in topsoil (O and A) and subducted topsoil horizons (Ojij and Ajj), respectively. The large stock of 19 ± 6 kg m\(^{-2}\) OC in subsoil horizons (82 ± 27% of the total OC) highlights the relevance of subsoil environments for storing large quantities of OM.

**Density fractions and mineralogical controls on carbon accumulation**

Density fractionation revealed that 19 ± 10% of the bulk OC in mineral soil horizons was present as POM. The largest proportion of POM-C was found in subducted topsoils as well as permafrost horizons (Table 3). The fraction of OC bound to minerals (MOM) accounted for 62 ± 13% of the bulk OC, with no significant differences between the soil horizon classes (ANOVA; Table S2, File S1; mean values Table 3). Despite the good recovery of soil mass (96 ± 2%), 19 ± 14% of the total OC was mobilized during density fractionation, with the smallest proportions in subducted topsoil horizons (8 ± 4%). Whereas 2 – 13% (0.1 – 0.4 mg g\(^{-1}\)) of the MoF can be attributed to initial DOC in mineral horizons (Table 3), most of it results from the SPT-induced desorption of OM from mineral-organic associations (Gentsch et al., 2015). Nevertheless, the MOM fraction was the dominant OC pool, holding 54 ± 16% of OC in the upper 100 cm of the pedon, with an even larger share (64 ± 18%) in subsoil horizons (Table S1, File S1).

Mineral-associated OC was strongly related to the clay content \(R^2 = 0.80\); \(P < 0.01\) and Al\(_p\) concentrations \(R^2 = 0.82\); \(P < 0.01\), as well as to Fe\(_p\) and Al\(_p\) concentrations \(R^2 = 0.90\) and 0.91, respectively; \(P < 0.001\). Weaker linear relationships were observed with Fe\(_o\) \(R^2 = 0.37\); \(P < 0.01\) and Fe\(_p\) concentrations \(R^2 = 0.60\); \(P < 0.01\). Figure 4 shows that across all pedons the molar concentration of mineral-associated OC plotted against those of Fe\(_p\) + Al\(_p\) is a straight line with a slope of 0.0181 ± 0.0004 \(N = 85\), which translates into an overall molar (Fe + Al):C ratio of 0.02. This result suggests that MOM in the tundra soils is ‘proportionally’ loaded with Fe and Al depending on the amount of OM present,
A linear regression between the moles of Fe$_{p}$ + Al$_{p}$ and the mass of MOM (OC-OM conversion factor, 1.7) results in a slope of 9 × 10^{-4} ± 2 × 10^{-5} mol [Fe$_{p}$ + Al$_{p}$] g$^{-1}$ OM, which is in the reported range of Fe concentrations that can be complexed by humic substances at pH 5–7 (10^{-3} to 10^{-4} mol g$^{-1}$; Tipping et al., 2002). These estimates show that under the arctic conditions sufficient mineral weathering must take place to produce dissolved Fe and Al concentrations large enough to saturate the remaining available binding sites of the MOM. Moreover, the molar (Fe$_{p}$ + Al$_{p}$):C ratio of 0.02 is close to the metal:C ratio of 0.03–0.05 at which significant precipitation of metal-organic complexes has been reported (see review by Kleber et al., 2015). Therefore, apart from adsorption of DOC onto mineral surfaces, another conceivable pathway in the formation of mineral-organic associations in permafrost soils involves the formation of Fe and Al co-precipitates, which represent variable mixtures of insoluble metal-organic complexes and poorly ordered mineral phases (Kleber et al., 2015).

As a result of the temporal anoxic conditions in the Kolyma lowland soils and the reductive dissolution of Fe(III) oxides and Fe(III) in phyllosilicates (Vodyanitskii et al., 2008), Fe$_{aq}^{3+}$ accumulates in the active layer as the permafrost table impedes drainage (Alekseev et al., 2003). Upon aeration, Fe$_{aq}^{3+}$ becomes re-oxidized to Fe$^{3+}$ and precipitates with dissolved OM as either Fe-organic complexes and

irrespective of the soil horizon considered. Table 3 Organic C and TN concentrations of the bulk soil and OM fractions received from density fractionation

Figure 5 Bulk soil relationships between (a) δ¹³C and C:N ratios and (b) δ¹⁵N and C:N ratios, as well as between (c) the δ¹³C and δ¹⁵N isotopic ratios across all examined pedons. (d–f) Show the relationship between the δ¹³C and C:N ratio of mineral-associated (cycles) and particulate OM (stars) under different tundra vegetation. Note, C:N ratios below about five as observed for some samples at the shrubby grass tundra site (d) imply a contribution from inorganic N.

There was a general decrease in the C:N ratio of bulk OM from organic layers to topsoil mineral horizons, subsoil horizons and to the permafrost (Figure 5; Schnecker et al., 2014), indicating a preferential loss of carbon relative to nitrogen. The decline of C:N ratios was accompanied by an enrichment of both ¹³C and ¹⁵N (Figure 5a, b), suggesting an on-going decomposition and subsequent enrichment of isotopically heavy microbial products with soil depth. Likewise, Nadelhoffer et al. (1996) observed a 2–5‰ increase in δ¹⁵N within the top 20–30 cm of moist sedge and tussock tundra soils in Alaska. When examining the MOM and POM fractions individually, the linear relationships between the C:N ratios and δ¹³C values persisted but the POM consistently had more scatter than the MOM (Figure 5d–f). Combining all bulk samples (including organic layers and mineral horizons; N = 100) demonstrated a significant linear relationship between δ¹³C and δ¹⁵N with a slope of 1.07 ± 0.08 (Figure 5c), suggesting that in the tundra soils studied, C and N transformation processes are tightly coupled. Although N losses from permafrost-affected soils are negligible because of poor drainage and efficient N cycling, N transformation processes (ammonification, nitrification and denitrification) occur at slow rates (Wild et al., 2013), which is also indicated by the presence of [NO₃ + NH₄]-N in our soils (data not shown). Because nitrification, denitrification and enzymatic hydrolysis discriminate against ¹⁵N by the preferential use of ¹⁴N, the residual OM will become enriched in ¹⁵N. Mycorrhizal activity might also cause N isotope fractionation, but as fungal biomass at the study sites declines with soil depth (Gittel et al., 2014), fungal activity cannot explain the increase in ¹⁵N with soil depth. Therefore, it is more reasonable to assume that the declining dilution with isotopically lighter POM, as well as the slow but persistent OM transformation over time, caused the enrichment of ¹³C and ¹⁵N in older OM at greater depth (¹⁴C data see Figure 6).

As the δ¹³C values of MOM were significantly larger and C:N ratios smaller (P < 0.001; N = 84) than for POM, microbial-derived ¹³C- and N-enriched compounds provide an important source for the formation of MOM.

Two soil profiles were investigated for ¹⁴C activities of OM density fractions. The MOM had mean ¹⁴C activities ranging from 88.0 pMC (1060 years BP) to 34.9 pMC (8410 years BP) and was 150–3000 years older than the respective POM (Figure 6). Although the soils are characterized by cryogenic activity, the ¹⁴C activity of the MOM declined conventionally with soil depth.
Organic matter stabilization in permafrost soils

Figure 6 $^{14}$C activity of mineral-associated (MOM) and particulate OM (POM) in two soil profiles (profile A (a) and D (b); Table 1) under shrubby grass and tussock grass vegetation as an approximate function of soil depth. Analytical errors are smaller than the symbols; one POM fraction in the lower panel could not be measured because of insufficient amounts.

The presence of younger POM (309 years BP) in the deep Cgjj horizon (Figure 6, lower panel) resulted from its incorporation from adjacent subducted topsoil pockets. This suggests that cryogenic mass exchange transfers younger POM to the subsoil while ‘fresh’ dissolved OM appears not to be leached directly from topsoil into the subsoil, which would have caused a rejuvenation of the subsoil MOM. The existing difference in $^{14}$C activity between POM and MOM in most horizons, however, mirrors the stabilization of OM by the formation of mineral-organic associations.

Chemical composition of OM fractions

The $^{13}$C-NMR spectroscopy showed that in comparison with organic soil layers, both MOM and POM were depleted in O-/N-alkyl C but enriched in aryl C (Table S3, File S1). Nevertheless, O-/N-alkyl C as contained in polysaccharides constituted the dominant fraction of MOM, followed by aryl C and alkyl C (Figure 7). Compared with POM, the MOM fraction was slightly but significantly depleted in aryl C ($P = 0.024; N = 9$) but tended to contain more O-/N-alkyl C ($44 \pm 3\%$), alkyl structures ($30 \pm 5\%$) and carboxyl/amide C ($9 \pm 5\%$).

An increasing transformation of OM with soil depth was reflected by the increasing alkyl C/(O-/N-alkyl C) ratio in POM and MOM in all observed profiles (Table S3, File S1). Together with the narrower C:N ratios and the $^{13}$C/$^{15}$N enrichment with soil depth this also reflects the ongoing degradation of the POM and contribution of microbial products to the MOM, such as cell wall remains and lysis products or extracellular polymeric substances. The ratio of O-alkyl C as derived from C2, C3 and C5 signals of carbohydrates (70–75 ppm) to the methoxyl C signal of lignin (52–57 ppm) serves as another indirect proxy of OM decomposition (Bonanomi et al., 2013). The increase of the (70–75 ppm):(52–57 ppm) ratio with soil depth (Table S3, File S1) suggests that in comparison to the organic layers, both POM and MOM were depleted in carbohydrates, implying a preferential degradation of carbohydrates once OM enters the mineral soil, while lignin is selectively preserved.

Under anaerobic conditions lignin is apparently not biodegradable by fungi or lignin-decomposing Actinobacteria and other bacteria present in permafrost soil (Gittel et al., 2014) and requires at least temporarily oxic conditions. Gittel et al. (2014), however, identified some anaerobic lignin-degrading bacteria in the study soils but their activity is presumably slow. The greater proportion of aryl components in MOM than in the organic topsoil can, in addition to biological processes, be explained by the retention of lignin-containing DOC, which forms stronger surface complexes with minerals than hydrophilic OM rich in carbohydrates and is more readily precipitated (Kleber et al., 2015). Höfle et al. (2013) also found in clay fractions from a tundra Gelisol that aryl components became more enriched in progressively older OM with increasing soil depth (0–30 cm) than carbohydrates.

We applied XPS as a complementary, non-destructive method, yielding information about carbon oxidation states at the outermost particle surfaces. Carbon 1s spectra (Figure 8) showed that the outermost MOM was composed of carbons primarily bonded in aliphatic and aromatic structures (type-I carbon; at $285 \pm 0.1\, eV; 52 \pm 8\%;\ N = 9$), followed by O–C (and N–C carbons) mainly located in polysaccharides (type-II carbon; at...
and proteins.

three bonds to O and N (O–C–O, C–O, C–N) as located primarily in polysaccharides (C–O, C–N), carbon making two bonds to oxygen (C=O, O–C–O), and carbon making three bonds to O and N (O–C=O, O=C–N) as present in carboxylic acids and proteins.

Figure 8 The XPS C1s spectra from the MOM fraction in a shrubby grass tundra pedon. Spectra are arranged from the top down with increasing soil depth and include the fitted carbon sub-components, the sum curve and the underlying measured spectrum (black line). The following carbon species were distinguished (all sample data summarized in Table S4, File S1): aliphatic and aromatic carbon (C–C, C=H, C–H), carbon making a single bond to O (or N) as located primarily in polysaccharides (C–O, C–N), carbon making two bonds to oxygen (C=O, O–C–O), and carbon making three bonds to O and N (O–C=O, O=C–N) as present in carboxylic acids and proteins.

286.5 ± 0.1 eV; 29 ± 5%). Carboxyl and amide carbons constituted about 8 ± 2% of total C (Table S4, File S1). Particles in subducted topsoil horizons contained more type-II carbons than those in either adjacent topsoil or subsoil horizons, suggesting that polysaccharides were more effectively protected against biodegradation in the subducted topsoils. The ratio of the type-(I) and type-(II) carbons indicated a similar trend to that observed for the NMR-based degradation ratios, with less oxidized carbon forms (aromatic and aliphatic C) increasing in deeper soil horizons (Table S4, File S1). All chemical characteristics, therefore, suggest that mineral-organic associations in the deep active layer contain a larger portion of microbial-derived OM, which agrees with the declining C:N ratios and increasing δ13C and δ15N bulk values with soil depth.

Potential bioavailability of organic matter fractions

Density fractionation generally affects the integrity of a given sample as it disperses soil particles, and thereby potentially enhances the spatial accessibility of OM for microbes, and causes loss of OC (MoF; Table 3). Because minerals stabilize OM by formation of chemical bonds between functional groups and the mineral surface (Kleber et al., 2015), OM recovered as MOM must, therefore, be held by stronger bonds than the MoF. Hence, we can test the potential bioavailability of the OM associated with minerals by using the > 1.6-g cm⁻³ soil fraction in an incubation experiment. When the different OM fractions, spanning a wide range of chemical compositions and 14C ages, were exposed to an active microbial community at 15°C (approximately the maximum topsoil temperature in the study area) for 90 days under optimal nutrient conditions, roughly 1.5–5% of the initial OC was mineralized. The total mineralization was significantly larger in mineral topsoil horizons than in any of the subsoil horizons (ANOVA [1], Tables S5 and S6, File S1). Because of minor deviations in the subsoil respiration, topsoil (AB, Figure 9) and subsoil horizons (Ajj, Bg/Cg/Cff, Figure 9) were clustered as two independent subsets. In topsoil horizons, the largest OC mineralization was with the POM fraction (4.4 ± 0.7%), followed by the bulk soil (3.8 ± 1.0%) and MOM fraction (3.1 ± 0.6%), although these differences were not statistically significant (ANOVA [2], Tables S5 and S6, File S1). In contrast, significant differences between treatments were observed in the subsoil (ANOVA [3], Tables S5 and S6, File S1), with the most mineralization occurring for the MOM fraction, followed by POM and bulk soil (2.5 ± 0.5, 1.9 ± 0.4 and 1.6 ± 0.2%).

The amount of respired carbon corresponds well with the fast cycling OM fraction as judged from a meta-analysis of long-term incubation data of circum-arctic soils (Schädel et al., 2013) and was also comparable to recent results reported for a 98-day biodegradation experiment with mineral soil horizons from Canadian Cryosols (Gillespie et al., 2014). We observed a respiration pulse from the bulk soil at the beginning of the experiment that can be assigned to an easily available OM fraction that was removed from the OM fractions during density fractionation. This large initial CO₂ flush reflects the greater bioavailability of the MoF. However, given that the bulk soils still contained the MoF-OC but the overall extent of OC mineralization was even less than that of the OM fractions, the carbon lost during the density fractionation either was not significantly more bioavailable than the remaining OM or it was well stabilized by the mineral phase and only became mobilized upon addition of SPT. The fit of a first-order decay model to CO₂ emission data showed equally valid results statistically as those for the total mineralization (Figure 10). The POM fractions had the largest mineralization rates compared with MOM and bulk material in the topsoil (ANOVA [4], Tables S5 and S6, File S1), while the LSD test (ANOVA [5], Tables S5 and S6, File S1) indicated significant differences between all treatments in the subsoil, with the fastest rates for the MOM fraction, followed by POM and the bulk soil. The NMR-based O-alkyl C:methoxyl C ratio of the MOM fraction as judged from a meta-analysis of long-term cycling OM fraction as judged from a meta-analysis of long-term incubation data of circum-arctic soils (Schädel et al., 2013) and was also comparable to recent results reported for a 98-day biodegradation experiment with mineral soil horizons from Canadian Cryosols (Gillespie et al., 2014). We observed a respiration pulse from the bulk soil at the beginning of the experiment that can be assigned to an easily available OM fraction that was removed from the OM fractions during density fractionation. This large initial CO₂ flush reflects the greater bioavailability of the MoF. However, given that the bulk soils still contained the MoF-OC but the overall extent of OC mineralization was even less than that of the OM fractions, the carbon lost during the density fractionation either was not significantly more bioavailable than the remaining OM or it was well stabilized by the mineral phase and only became mobilized upon addition of SPT. The fit of a first-order decay model to CO₂ emission data showed equally valid results statistically as those for the total mineralization (Figure 10). The POM fractions had the largest mineralization rates compared with MOM and bulk material in the topsoil (ANOVA [4], Tables S5 and S6, File S1), while the LSD test (ANOVA [5], Tables S5 and S6, File S1) indicated significant differences between all treatments in the subsoil, with the fastest rates for the MOM fraction, followed by POM and the bulk soil. The NMR-based O-alkyl C:methoxyl C ratio of the MOM fraction was related to the mineralization rate constant (R² = 0.37; P < 0.05; N = 9) and suggests that MOM rich in carbohydrates (topsoil horizons) decomposed faster than that containing more lignin compounds in the subsoil.

Implications of the incubation experiment and controlling factors

Despite the larger accessibility of OM and the optimal temperature and nutrient conditions in this experiment, the MOM largely resisted microbial decomposition. The total amount of respired...
Organic matter stabilization in permafrost soils

Figure 9 Cumulative OC mineralization of mineral-associated (MOM) and particulate OM (POM) and bulk soil material (bulk). Whiskers are sometimes smaller than symbols and show the SD. Sample numbers (N) of bulk soil and MOM including replicates were: AB, N = 9; Ajj, N = 24; BCg, N = 12; Cg/Cff, N = 9; and for the POM fraction: AB, N = 3; Ajj, N = 24; Cg/Cff, N = 3.

Figure 10 Observed first-order decay rate constants from 90-day incubation experiments for OM fractions and the bulk soil (N equals those in Figure 9).

OC was in a lower range than that from laboratory incubation studies with soil heavy density fractions or artificial mineral-organic associations (Table S7, File S1). Jagadamma et al. (2013) found only slight differences in the decomposability of POM and MOM from a Gelisol after 150 days incubation (about 10% of total OC mineralized), with the MOM fraction being mineralized faster than the POM fraction. In laboratory incubations, a stabilizing effect of the mineral phase on mineral-bound OM is often inferred from decomposition rates that are less than those for the respective unprotected OM that is not adsorbed or precipitated. For tundra sites in Alaska, Michaelson et al. (1998) reported that DOC, as a potential source of MOM, leached from thawing soil cores (pH 4.6 and 7.3) was primarily composed of polysaccharide-rich components and bioavailable, losing 34–46% of C in a 14-day incubation at 4°C. Hence, DOC from permafrost soils appears to be much more vulnerable to decomposition than our MOM fractions. The fact that the O-alkyl C:methoxyl C ratio of MOM was positively related to the mineralization rate constant agrees with the view that aromatic-rich dissolved OM is intrinsically more resistant to biodegradation than carbohydrate-rich OM and also interacts more strongly with minerals, resulting in less desorption and, therefore, mineralization (Kleber et al., 2015). Gillespie et al. (2014) also found a larger mineralization potential for OM from Cryosol B horizons, which comprised more carbohydrate C relative to ketone C. However, they suggested that lignin-derived phenolics likewise represented a labile OM source. The negative relationship between decomposition rates and the Fe₃⁺:Fe₄ ratio (R² = 0.41; P < 0.01; N = 18) implies that organically complexed Fe rather than the whole pedogenic Fe pool reduces the bioavailability of mineral-bound OM, probably by minimizing the solubility in Fe-OM co-precipitates.
The extremely slow decomposition of POM in the subsoil is surprising and probably occurs because the easily available C necessary to stimulate microbial breakdown had already been leached or consumed by the decomposers during its longer residence time (Figure 6). A lack of easily available C (and N) has been demonstrated in priming experiments, particularly for the subsoil horizons (Wild et al., 2014). The poor bioavailability of MOM, which is comparable to that in other climates (Table S7, File S1), is surprising given the less optimal soil conditions for the formation of stable mineral-organic associations in permafrost soils. The pH value (pH 5–8; Table 2), which is close to the point of zero charge of Fe and Al oxides (pH 7–9), theoretically diminishes the effective sorption and stabilization of OM on the surface of these minerals or clay edges. The aquic conditions (Vodyanitskii et al., 2008) accompanied by reductive dissolution of Fe(III) oxides in permafrost soils should also not favour the effective stabilization of OM by Fe oxides. The restricted decomposability of MOM even under optimal conditions, however, in addition explains the formation of large MOM stocks and small 14C activities (between 0.82 and 0.35 pMC) in the soil that we studied.

Conclusions

This study confirms that OM in permafrost-affected tundra soils is not ‘inactivated’ but microbially transformed over thousands of years under unfavourable conditions, leading to a large fraction of 13C and 15N-enriched OM associated with minerals and to an enrichment of alkyl and aromatic compounds with soil depth. The build-up of the large MOM pool (54 ± 16% of the total soil OC) in these permafrost soils is the result of multiple processes, including the adsorption of DOC or microbial remnants to clay minerals and Al and Fe oxides (with a stronger emphasis on Al phases) as well as the co-precipitation of DOC, which is a yet under-rated mechanism in permafrost soils. Although the majority of MOM was not readily available under the optimal temperature and nutrient conditions, it contains a biologically active OM pool (<5%) that can be used by microorganisms. The finding of less bioavailable POM in the subsoil than in the topsoil is indicative of the limited energy-rich C sources required for microbial decomposition in deep soil horizons. An increasing input of easily available OM has been claimed as being responsible for stimulation of microbial activity in mineral subsoil in a 20-year soil warming experiment (Sistla et al., 2013) and recent priming experiments (Wild et al., 2014). For our results, this suggests that a part of this activity results from the use of mineral-bound OM under the ‘neutral’ soil conditions. We assume that as well as freezing and water-logging, stabilization of OM by associations with minerals is one key mechanism for OM conservation in arctic permafrost soils, which might become increasingly important with a future rise in soil temperatures and drier conditions. Given the abundance of a bioactive OC fraction, future research should not ignore the function and fate of mineral-organic associations, which hold the dominating OC pool in mineral horizons of permafrost soils.
